Nuclear reactors provide intense sources of electron antineutrinos, characterized by few-MeV energy E and unoscillated spectral shape $\Phi(E)$. High-statistics observations of reactor neutrino oscillations over medium-baseline distances $L \sim \mathcal{O}(50)$ km would provide unprecedented opportunities to probe both the long-wavelength mass-mixing parameters (δm^2 and θ_{12}) and the short-wavelength ones (Δm_{ee}^2 and θ_{13}), together with the subtle interference effects associated to the neutrino mass hierarchy (either normal or inverted). In a given experimental setting—here taken as in the JUNO project for definiteness—the achievable hierarchy sensitivity and parameter accuracy depend not only on the accumulated statistics but also on systematic uncertainties, which include (but are not limited to) the mass-mixing priors and the normalizations of signals and backgrounds. We examine, in addition, the effect of introducing smooth deformations of the detector energy scale, $E \rightarrow E'(E)$, and of the reactor flux shape, $\Phi(E) \rightarrow \Phi'(E)$, within reasonable error bands inspired by state-of-the-art estimates. It turns out that energy-scale and flux-shape systematics can noticeably affect the performance of a JUNO-like experiment, both on the hierarchy discrimination and on precision oscillation physics. It is shown that a significant reduction of the assumed energy-scale and flux-shape uncertainties (by, say, a factor of two) would be highly beneficial to the physics program of medium-baseline reactor projects. Our results shed also some light on the role of the inverse-beta decay threshold, of geoneutrino backgrounds, and of matter effects in the analysis of future reactor oscillation data.

I. INTRODUCTION

The currently established neutrino oscillation phenomenology can be interpreted in a three-generation framework, whose relevant parameters are three mixing angles (θ_{12} , θ_{13} , θ_{23}), one possible CP-violating phase δ , and two neutrino squared mass differences (δm^2 , $\pm \Delta m^2$), where the latter sign distinguishes the cases of normal hierarchy (NH, +) and inverted hierarchy (IH, −) for the neutrino mass spectrum [1]. In reactor neutrino experiments, for a given neutrino energy E and baseline L , the $\bar{\nu}_e$ disappearance probability depends only on a subset of parameters,

$$P(\bar{\nu}_e \rightarrow \bar{\nu}_e) = P_{ee}(\theta_{13}, \theta_{12}, \delta m^2, \pm \Delta m^2), \quad (1)$$

and is generally not invariant under a swap of the Δm^2 sign, thus providing some sensitivity to the mass hierarchy as noted in [2]. Hierarchy effects vanish in the limits of short baselines [$L \lesssim \mathcal{O}(1)$ km] and of long baselines [$L \gtrsim \mathcal{O}(10^2)$ km], where the P_{ee} arguments reduce to $(\theta_{13}, |\Delta m^2|)$ and $(\theta_{13}, \theta_{12}, \delta m^2)$, respectively. However, at medium baselines L (few tens of km), the hierarchy sensitivity can be recovered in high-statistics reactor experiments, provided that interference effects between short- and long-wavelength oscillations are resolved, as originally proposed in [3].

Such a possibility is being seriously investigated experimentally, as one of the main physics goals of the Jiangmen Underground Neutrino Observatory in China [4] (JUNO, in construction), and of the project RENO-50 proposed in Korea [5]. A number of papers have examined the stringent conditions needed to discriminate the hierarchy in this class of reactor experiments, including high energy resolution, small dispersion of multiple core baselines, good control of energy-scale nonlinearities, and reduction of systematics related to oscillation parameters and normalizations. Satisfying these conditions would also provide more precise measurements of the parameters (θ_{12} , δm^2) [6] and of Δm^2 . We refer the reader to [7, 8] for recent reviews of this field of research and of the related bibliography.

In this context, it has been realized that the shape of the (unoscillated) reactor neutrino flux $\Phi(E)$ may not be known with the desirable accuracy, as recently demonstrated by the unexpected spectral features consistently found in the current short-baseline experiments RENO [9], Double Chooz [10] and Daya Bay [11]. In particular, an event excess (sometimes dubbed as a “bump” or “shoulder” in the spectrum) clearly emerges around $E \sim 5\text{--}7$ MeV, with respect to widely adopted theoretical predictions [12, 13]. Very recent calculations provide possible (although still partial) interpretations of the subtle nuclear effects which may be responsible for these (and possibly other) unexpected spectral features [14–16], but a thorough understanding of their origin has not been achieved yet.

In current short-baseline experiments, endowed with near and far detectors, poorly understood spectral features largely cancel in near-to-far flux ratios, and do not significantly affect the measurement of the dominant parameters

($\theta_{13}, |\Delta m^2|$) [17]. However, in the absence of a near detector, a medium-baseline experiment such as JUNO must rely on absolute estimates of the flux spectrum $\Phi(E)$ and of its associated uncertainties, which may affect both the sensitivity to the hierarchy and the accuracy of the ($\theta_{12}, \delta m^2, |\Delta m^2|$) measurements.

A related and subtle issue concerns energy-scale variations $E \rightarrow E'(E)$ which, in principle, may be nonlinearly engineered to produce a hierarchy ambiguity [18]. Although the energy-scale issue can be kept under control by calibration constraints at sub-percent level [19], specific combinations of energy variations $E \rightarrow E'(E)$ and spectral deviations $\Phi(E) \rightarrow \Phi'(E)$ might represent a more subtle threat to the hierarchy discrimination [20]. In general, delicate statistical aspects—related to the treatment of admissible spectral deformations—are now emerging in neutrino oscillation searches, mirroring the evolution of other fields of physics from the discovery phase to the precision era, as remarked in [21].

Within this scenario, and building upon our previous work [20], we present herein a systematic analysis of the combined effects of energy-scale nonlinearities $E \rightarrow E'(E)$ and flux-shape uncertainties $\Phi(E) \rightarrow \Phi'(E)$, assuming a reference JUNO-like medium-baseline reactor neutrino setting. The structure of our paper is as follows: In Sec. II we describe the adopted notation and methodology. In Sec. III we discuss the effects of energy-scale and flux-shape uncertainties on the hierarchy discrimination, while in Sec. IV we show their impact on precision measurements of the oscillation parameters. In Sec. V we repeat the analysis in a prospective scenario where the energy-scale and flux-shape uncertainties are reduced by a factor of two. We also comments on the role of the inverse-beta decay threshold, geoneutrino backgrounds, and matter effects. A brief summary of the results, and perspectives for further work, are presented in Sec. VI.

II. NOTATION AND METHODOLOGY

We generally adopt the same notation and inputs as in [20] (to which the reader is referred for details), and comment below only about those aspects which are new, modified, or relevant for the present analysis. In particular, we discuss the statistical approach used to characterize and include energy-scale and flux-shape uncertainties. We remark that the adopted experimental set-up [20], as taken from [19], is basically the same as reported in a recent publication from the JUNO collaboration [4].

A. Neutrino oscillation parameters and priors

Neutrino oscillation probabilities can be expressed in terms of neutrino squared mass differences ($\Delta m_{ji}^2 = m_j^2 - m_i^2$) and trigonometric functions of the mixing angles θ_{ij} (e.g., $s_{ij} = \sin \theta_{ij}$, $c_{ij} = \cos \theta_{ij}$). In medium-baseline reactor experiments, there are four relevant parameters: s_{12}^2 , s_{13}^2 , $\delta m^2 = \Delta m_{21}^2$, and Δm_{ee}^2 defined as [22–24]

$$\Delta m_{ee}^2 = \Delta m^2 \pm \frac{1}{2}(c_{12}^2 - s_{12}^2)\delta m^2, \quad (2)$$

where the upper (lower) sign refers to NH (IH), while Δm^2 is defined as [20, 25]

$$\Delta m^2 = \frac{1}{2} |\Delta m_{31}^2 + \Delta m_{32}^2| > 0. \quad (3)$$

An accurate analytical expression for the oscillation probability P_{ee} , including effects due to propagation in constant-density matter and to multiple reactor cores, can be found in [20] [see Eqs. (58) and (59) therein].

We assume the following reasonable priors (central values and $\pm 1\sigma$ errors) for the above parameters, at the start of a JUNO-like experiment:

$$s_{12}^2 = (3.08 \pm 0.17) \times 10^{-1}, \quad (4)$$

$$\delta m^2 = (7.54 \pm 0.20) \times 10^{-5} \text{ eV}^2, \quad (5)$$

$$s_{13}^2 = (2.20 \pm 0.08) \times 10^{-2}, \quad (6)$$

$$\Delta m_{ee}^2 = (2.40 \pm 0.05) \times 10^{-3} \text{ eV}^2. \quad (7)$$

The ($s_{12}^2, \delta m^2$) priors—unlikely to change significantly in the near future—are taken from the global fit in [20], with errors defined as 1/6 of the $\pm 3\sigma$ range. The s_{13}^2 central value is a bit lower than in [20], as suggested by recent reactor results [5, 10, 17], and is also endowed with a smaller $\pm 1\sigma$ error, representative of the final accuracy expected in Daya Bay [26]. Finally, the Δm_{ee}^2 central value is also in ballpark of the current global fits [20], but with a somewhat smaller fractional error (2.0% instead of 2.6%) as it can be expected from near-future improvements in short-baseline reactor [26] and long-baseline accelerator experiments [27].

B. Reactor and geoneutrino spectra, energy resolution and thresholds

Concerning the reactor neutrino fluxes (from both medium-baseline and far sources), we use the same average fuel component and overall normalization as in [20], but we alter the energy profile to include the newly discovered spectral feature at $E \sim 5\text{--}7$ MeV [9–11]. In particular, we multiply the unoscillated reactor spectrum in [20] by a smoothed version of the bin-to-bin ratio (Daya Bay)/(Huber + Mueller) reported in [26], which effectively accounts for the spectral “bump” feature as observed in Daya Bay [11].

The normalization of the U and Th geoneutrino background fluxes in JUNO is slightly increased with respect to [20] by 7% and 9%, respectively, in order to match the most recent estimates in [28]. We also update the associated errors, by conservatively taking the largest of the asymmetric 1σ uncertainties from [28], namely, $\pm 20\%$ for the U flux and $\pm 27\%$ for the Th flux.

Finally, with respect to [20], we slightly update the energy resolution width σ_e as reported in [26],

$$\frac{\sigma_e(E_e)}{E_e + m_e} = \frac{2.57 \times 10^{-2}}{\sqrt{(E_e + m_e)/\text{MeV}}} + 0.18 \times 10^{-2}, \quad (8)$$

where $E_e + m_e$ is the total (true) visible energy of the inverse beta decay (IBD) event, as a sum of the total positron energy E_e and electron mass m_e . We remind the reader that [20]: (1) the finite resolution width smears the observed visible energy E_{vis} around its true value $E_e + m_e$; (2) the neutrino energy E has an IBD kinematical threshold $E \geq 1.806$ MeV; (3) the parent neutrino energy E and the observed visible energy of the event E_{vis} are approximately related by

$$E \simeq E_{\text{vis}} + 0.78 \text{ MeV}, \quad (9)$$

up to nucleon recoil and energy resolution effects (which we accurately include in the calculations of energy spectra [20]); and (4) the visible energy threshold is thus $E_{\text{vis}} \gtrsim 1$ MeV.

C. Error bands for energy-scale and flux-shape deformations

In first approximation, we assume a JUNO energy-scale uncertainty comparable to the Daya Bay one. For current Daya Bay data, the 1σ error band of admissible deviations in the reconstructed/true visible energy ratio has been shown in [17] and (with slightly smaller width) in [29, 30]. We have translated the bands in [29, 30] into relative deviations E'/E for the neutrino energy via Eq. (9). Asymmetric 1σ uncertainties have been symmetrized to the largest between $+1\sigma$ and -1σ . Figure 1 (top panel) shows, in color, the resulting energy-scale error band (at $\pm 1\sigma$ in E'/E), as a function of the parent neutrino energy E . Besides this “default” band, we shall also consider a more optimistic case with “halved” errors (dot-dashed lines in the top panel of Fig. 1), in view of dedicated energy calibration campaigns expected in JUNO.

FIG. 1: Default $\pm 1\sigma$ error bands assumed for energy-scale deviations E'/E (top panel) and flux-shape variations Φ'/Φ (bottom panel), in terms of the neutrino energy E . Bands with halved errors are also shown (dot-dashed lines in both panels).

Concerning the flux-shape uncertainties of the unoscillated reactor spectrum $\Phi(E)$, we assume that $\Phi'(E)/\Phi(E)$ deviations are constrained by the $\pm 1\sigma$ error bands estimated in [14]. We have smoothed out and symmetrized the bands in [14], as reported in Fig. 1 (bottom panel) in terms of the neutrino energy E . Since the issue of reactor spectral shapes is still highly debated, the Φ'/Φ error band should be taken as merely indicative of the current level of theoretical uncertainties. The high statistics accumulated in the present generation of short-baseline reactor experiments will certainly help to constrain any model of reactor spectra and, indeed, the current size of systematic shape uncertainties estimated in Daya Bay [17] seems to be already a factor of two smaller than in [14], although a detailed assessment has not been published yet. For this reason, also in the analysis for flux-shape uncertainties, we shall consider the more optimistic case of “halved” theoretical errors (dot-dashed lines in the bottom panel of Fig. 1).

A final remark is in order. In the absence of a detailed characterization of the error bands in Fig. 1, we simply assume that they scale linearly with $n\sigma$. We also neglect, for lack of published information, possible error correlations at different energies. Although some correlations are known to exist, as a result of underlying models for both the energy scale nonlinearities [17, 29, 30] and the reactor spectra [12–15], their impact should not be overemphasized at this stage. Indeed, the recently observed, localized “bump” feature largely exceeds the estimated errors and covariances that were thought to characterize the spectra a few years ago [12, 13]. In this sense, neglecting possible covariances in Fig. 1 should lead to conservative results. A more refined analysis will be possible when such error bands will be determined more precisely, and endowed with point-to-point correlation functions.

D. Statistical approach

As in [20], we calculate the “true” event spectrum $S^*(E_{\text{vis}})$ by assuming the central values of the oscillation parameters reported in Sec. II A, for either NH or IH. Such a spectrum S^* represents the “experimental data”, to be compared with a family of spectra $S(E_{\text{vis}})$, obtained by varying the continuous parameters (δm^2 , Δm_{ee}^2 , θ_{12} , θ_{13}), in either the same or the opposite hierarchy. The comparison is performed in terms of a χ^2 function which contains statistical, parametric, and systematic components,

$$\chi^2 = \chi_{\text{stat}}^2 + \chi_{\text{par}}^2 + \chi_{\text{sys}}^2. \quad (10)$$

The χ_{stat}^2 term (which embeds statistical fluctuations) is the same as in [20]. The χ_{par}^2 term (which embeds penalties for the oscillation parameters) is also unchanged, apart from the numerical priors, here taken from Sec. II A above.

The χ_{sys}^2 term contains, as in [20], two penalties related to the geoneutrino flux normalizations,

$$\chi_{\text{geo}}^2 = \sum_{j=\text{U,Th}} \left(\frac{f_j - 1}{s_j} \right)^2 \in \chi_{\text{sys}}^2, \quad (11)$$

where we take $s_{\text{U}} = 0.20$ and $s_{\text{Th}} = 0.27$, as described in Sec. II B. However, while in [20] the χ_{sys}^2 term was completed by just another penalty for the overall reactor flux normalization, now it must be supplemented by appropriate penalties for energy-scale and flux-shape deformations.

To this purpose, we consider smooth deformations of the energy scale $E \rightarrow E'(E)$ (that we assume to act upon the “experimental spectrum” S^*) and of the flux shape $\Phi(E) \rightarrow \Phi'(E)$ (that we assume to act upon the “theoretical spectrum” S), in terms of generic polynomials in E (in MeV),

$$\frac{E'}{E} = 1 + \sum_{i=0}^k \alpha_i E^i = 1 + \delta_E(E), \quad (12)$$

$$\frac{\Phi'(E)}{\Phi(E)} = 1 + \sum_{j=0}^h \beta_j E^j = 1 + \delta_\Phi(E), \quad (13)$$

with h and k increasing until stable results are reached [31]. Note that the trivial cases $h = 0$ and $k = 0$ correspond, respectively, to an overall renormalization of the energy scale [$E' = (1 + \alpha_0)E$] and of the reactor spectrum [$\Phi' = (1 + \beta_0)\Phi$].

With reference to Fig. 1, let us denote the boundaries of the 1σ error bands in Fig. 1 as $1 \pm S_E(E)$ for the upper panel, and as $1 \pm S_\Phi(E)$ for the lower panel. Then we define two new systematic penalties, in terms of the largest relative deviation associated to each polynomial:

$$\chi_E^2 = \max_E \left| \frac{\delta_E(E)}{S_E(E)} \right|^2, \quad (14)$$

$$\chi_{\Phi}^2 = \max_E \left| \frac{\delta_{\Phi}(E)}{S_{\Phi}(E)} \right|^2. \quad (15)$$

In other words, if the polynomial function $\delta_E(E)$ “touches” the $n\sigma$ error band boundary $n \times S_E(E)$, its contribution to the χ_{sys}^2 term is assumed to be n^2 , and similarly for $\delta_{\Phi}(E)$ and $S_{\Phi}(E)$. Equivalently, the $\pm 1\sigma$ bands in Fig. 1 are assumed to be the envelope of all possible systematic deviations at the 1σ level, and similarly for $n\sigma$. Such a χ^2 characterization of energy-scale and spectral-shape errors is both intuitive and conservative, as appropriate to an exploratory analysis. As previously remarked, more refined definitions of χ_{sys}^2 will be possible in the future, in terms of energy-dependent cross-correlations.

We have found that our results, to be discussed in the next sections, become numerically stable already for fifth-order polynomials, which are taken as a default choice for all the following figures. Therefore, in general, the χ^2 minimization requires scanning a 18-dimensional parameter space, including four oscillation parameters ($s_{12}^2, s_{13}^2, \delta m^2, \Delta m_{ee}^2$), two geoneutrino flux normalizations (f_U, f_{Th}), and twelve polynomial coefficients ($\alpha_0, \dots, \alpha_5$) and (β_0, \dots, β_5). [We have also cross-checked the numerical results by using different and independent minimization methods.]

For the sake of the discussion, we shall also consider cases with reduced dimensionality, as obtained by setting to zero the coefficients α_i or β_j . However, in our analysis, the specific coefficient β_0 is never zeroed a priori, since it parametrizes a floating normalization for the reactor flux, $\Phi \rightarrow \Phi(1 + \beta_0)$. In particular, we shall consider the following cases, in order of increasing number of free parameters:

- oscillation + normalizations: $(s_{12}^2, s_{13}^2, \delta m^2, \Delta m_{ee}^2) + (f_U, f_{\text{Th}}) + (\beta_0) = 7$ parameters;
- osc. + norm. + energy scale: as above + $(\alpha_0, \dots, \alpha_5) = 13$ parameters;
- osc. + norm. + energy scale + flux shape: as above + $(\beta_1, \dots, \beta_5) = 18$ parameters.

In the first two cases, from the definition of χ_{Φ}^2 , the 1σ error associated to β_0 coincides to the smallest error band width in Fig. 1 (bottom panel), i.e. to $\sim 2.3\%$, which is a typical value for the reactor flux normalization uncertainty.

III. DEFAULT ENERGY-SCALE AND FLUX-SHAPE ERRORS: HIERARCHY TESTS

In this section we study the hierarchy sensitivity of the reference JUNO experiment, under the effects of increasingly large sets of systematic errors. Default 1σ errors are assumed for energy-scale and flux-shape deviations (see Fig. 1). The various effects are first shown graphically and then quantified in terms of the variable [32] $N_{\sigma} = \sqrt{\Delta\chi^2}$.

Figure 2 (upper panel) shows the absolute NH and IH event spectra S^{NH} and S^{IH} , respectively, as obtained by simply swapping the hierarchy, without any change in the central value of the oscillation parameters or other systematics (case of “no uncertainties”). For definiteness, the spectra correspond to 5 years of data taking. The lower panel of Fig. 2 shows the IH/NH spectral ratio, with characteristic wiggles due to the mismatch between the oscillation peak positions in the two hierarchies. The amplitude of the wiggles reaches $\sim 4\%$ for $E_{\text{vis}} \sim 2\text{--}3$ MeV. In this ideal situation, the NH and IH spectra would be distinguishable “by eye.”

In Fig. 3, the NH spectrum is taken as input data ($S^* = S^{\text{NH}}$), while the IH spectrum is fitted ($S = S^{\text{IH}}$), with allowance for oscillation parameter uncertainties and normalization systematics. With respect to Fig. 2, the mismatch between NH and IH spectra appears to be reduced to $\lesssim 3\%$ in the low-energy range, although it slightly increases (up to $\sim 1.5\%$) at high energy.

Figure 4 is similar to Fig. 3, but with energy-scale uncertainties included in the fit. In this case, the NH and IH spectra are barely distinguishable by eye, their relative mismatch being lower than $\sim 2\%$ at any energy. This trend is even more pronounced in Fig. 5, where flux-shape uncertainties have been included in the fit: the NH and IH spectra appear to be almost indistinguishable, except for percent-level differences in the oscillation peaks around 2 MeV.

In Figs. 2–5, a sharp rise of the event spectra is evident at the IBD threshold. The steep derivative guarantees that energy-scale and flux-shape deviations cannot be large at threshold, otherwise the spectral mismatch would locally “explode,” with a significant χ^2 increase. In this sense, the IBD threshold acts as a “self-calibrating point”: the “true” (NH) spectrum and the “test” (IH) spectrum must almost coincide at such kinematical threshold, and systematic errors in the fit cannot alter this requirement. [At most, the small residual mismatch around threshold may lead to locally fuzzy wiggles in the spectral ratio S^*/S , as partly shown in Figs. 4 and 5.]

The above expectations are confirmed by an analysis of the best-fit energy profiles (fifth-degree polynomials) for the energy-scale and flux-shape deviations, corresponding to the cases shown in Figs. 3, 4 and 5. Figure 6 shows such profiles (solid curves) superimposed to the default error bands (in color) for E'/E (top panels) and Φ'/Φ (bottom panels). The leftmost panels of Fig. 6 correspond to the fit in Fig. 3, which includes only oscillation and normalization errors. In this case, $E'/E = 1$ by construction (no energy-scale error), while $\Phi'/\Phi = 1 + \beta_0$ can float (to account for the flux normalization), but happens to have a best-fit value very close to unity.

FIG. 2: Comparison of event spectra in NH and IH, as obtained for fixed oscillation parameters and no systematic errors. Top: absolute spectra for $T = 5$ yr. Bottom: Spectral ratio.

FIG. 3: Comparison of event spectra in NH (true, S^*) and IH (fitted, S), including oscillation and normalization uncertainties.

FIG. 4: As in Fig. 3, but including energy-scale systematics.

FIG. 5: As in Fig. 4, but including flux-shape systematics.

The middle panels in Fig. 6 correspond to the fit in Fig. 4, which includes also energy-scale systematics. In this case, one can observe a slight offset of the overall ratio $\Phi'/\Phi = 1 + \beta_0$, and a peculiar pattern for the best-fit E'/E profile. The function E'/E is close to unity at the IBD threshold ($E \simeq 1.8$ MeV, equivalent to $E_{\text{vis}} \simeq 1$ MeV), according to expectations. Then the function rises up by $\sim +0.6\%$, changes sign at $E \simeq 4$ MeV, decreases by $\sim -0.6\%$, and approaches unity at high energy. The sign-flip behavior is vaguely reminiscent of the “engineered” E'/E profile which would realign, by construction, the IH and NH oscillation phases and peaks [18] while remaining unity at the IBD threshold (see Fig. 17 in [20]). However, the “fitted” E'/E profile in Fig. 6 does not need to reach large deviations at high E as the “engineered” one [20], since the high-energy tail of the spectrum contributes marginally to the χ^2 function. Finally, the rightmost panels in Fig. 6 correspond to the complete fit in Fig. 5, which includes also flux-shape systematics. The function E'/E is qualitatively similar to the middle panel, but with reduced deviations in the high-energy part of the spectrum. The best-fit function Φ'/Φ shows sign-changing deviations at the few-percent level, well within the $\pm 1\sigma$ (colored) error band. In conclusion, admissible systematic deformations of the energy scale and of the flux shape, added to the usual oscillation parameter and normalization uncertainties, may bring the “true” and “wrong” event spectra as close to each other as shown in Fig. 5.

FIG. 6: Energy profile of best-fit deviations E'/E (top panels) and Φ'/Φ (bottom panels), for different sets of systematic uncertainties.

Figure 7 shows the statistical significance of the wrong hierarchy rejection, for the case of true normal hierarchy, in terms of $N_\sigma = \sqrt{\Delta\chi^2}$ as a function of live time T . The abscissa scales as \sqrt{T} , thus showing at a glance any deviation from the ideal “linear” case of purely statistical errors ($N_\sigma \propto \sqrt{T}$). In the fit including only oscillation parameter and normalization uncertainties, N_σ grows steadily and almost linearly in \sqrt{T} along ten years of data taking. However, the inclusion of energy-scale uncertainties provides some bending of the linear rise, with a noticeable but not dramatic decrease of the statistical significance. In particular, it appears that a 3σ rejection is achievable after about six years of data taking. We agree with [19] that energy-scale uncertainties, by themselves, do not represent a showstopper for JUNO-like experiments. However, Fig. 7 shows that the combination of energy-scale and flux-shape systematics can be quite sizable: the solid curve for N_σ grows much more slowly than \sqrt{T} , and remains below 3σ even after ten years of data taking. Figure 8 shows a very similar behavior, but assuming the IH as true. Figure 7 and 8 represent one of

FIG. 7: Case of true NH: statistical significance of the IH rejection as a function of the detector live time T , as derived from fits including different sets of systematics. Note that the abscissa scales as \sqrt{T} . The horizontal 3σ line is shown to guide the eye.

FIG. 8: As in Fig. 7, but for true IH and rejection of NH.

FIG. 9: Mass-mixing parameters ($\delta m^2, s_{12}^2$): 1σ contours for true NH and $T = 5$ y, as derived from fits including different systematic uncertainties. The arrows indicate the best-fit displacement in the cases of wrong hierarchy (green) and no matter effects (magenta).

FIG. 10: As in Fig. 9, but for the $(\Delta m_{ee}^2, s_{13}^2)$ parameters.

IV. DEFAULT ENERGY-SCALE AND FLUX-SHAPE ERRORS: PRECISION PHYSICS

In this section, unless otherwise noticed, the true hierarchy is assumed to be known, and the discussion is focussed on the precision physics program, namely, on the accuracy expected at $\pm 1\sigma$ on the oscillation parameters and geoneutrino normalizations. For definiteness, the accumulated statistics refers to $T = 5$ y.

Figure 9 shows the 1σ contours in the plane charted by the mass-mixing parameters $(\delta m^2, s_{12}^2)$, assuming true NH. In the case with only oscillation and normalization errors, the accuracy of both δm^2 and s_{12}^2 is more than an order of magnitude better than the prior errors assumed in Sec. II A. The accuracy is slightly worse in the presence of energy-scale systematics, but is significantly degraded (by almost a factor of three) in combination with flux-shape systematics. This is not surprising, since the $(\delta m^2, s_{12}^2)$ parameters govern the long-wavelength oscillation pattern, which is sensitive to smooth deformations of the spectral shape. Note that, in all the above cases of Fig. 9, the best-fit coordinates coincide—by construction—with the central values of $(\delta m^2, s_{12}^2)$ assumed as priors. However, the best-fit point would be significantly displaced if the inverse hierarchy were mistakenly assumed as “true,” as indicated by the green arrow in Fig. 9 (color online). A different but still sizable displacement (indicated by the magenta arrow) would also be induced by discarding matter effects in the fit. For simplicity, the matter density has been assumed herein to be constant [20] but, in the future, one should characterize more precisely the density profile from the geophysical and geochemical viewpoint. Summarizing, Fig. 9 shows that the 1σ accuracy of the $(\delta m^2, s_{12}^2)$ measurements in a JUNO-like experiment can be significantly degraded by the combined effect of energy-scale and flux-shape uncertainties, and that their central values may be biased by ambiguities in the hierarchy, as well as by “vacuum” approximations in the oscillation probability.

Figure 10 shows the 1σ contours in the plane charted by the mass-mixing parameters $(\Delta m_{ee}^2, s_{13}^2)$, assuming true NH. The accuracy on s_{13}^2 is essentially constant and almost equal to the prior assignment in Sec. II A, implying that a JUNO-like experiment cannot really improve the input θ_{13} data from current short-baseline reactor experiment. In the case with only oscillation and normalization errors, the accuracy of Δm_{ee}^2 is more than an order of magnitude better than the prior error assumed in Sec. II A. However, the accuracy is degraded (by a factor of two) by energy-scale uncertainties and (by a factor of three) by adding flux-shape systematics. In fact these systematics, as shown in Sec. III, may slightly alter the pattern of short-wavelength oscillations and may thus affect the measurement of its peak frequency, governed by Δm_{ee}^2 . Moreover, the central value of Δm_{ee}^2 (but not of θ_{13}) would be strongly biased in the case of “wrong” hierarchy (green arrow), roughly by $(c_{12}^2 - s_{12}^2)\delta m^2$ as expected from Eq. (2). The vacuum approximation bias (magenta arrow) is instead insignificant, since the parameters $(\Delta m_{ee}^2, s_{13}^2)$ are basically unaffected by matter effects [20]. Results similar to Figs. 9 and 10 also hold in the case of true IH (not shown).

FIG. 11: As in Fig. 9, but for (Th, U) geo- ν normalizations.

Finally, Fig. 11 shows the 1σ contours in the plane charted by the Th and U geoneutrino flux normalizations (f_{Th} , f_{U}). The fit constrains these normalizations within 1σ errors which are smaller (by about 30%) than their prior values as defined in Sec. II D, and are quite insensitive to different sources of systematic errors and biases. Therefore, prospective geoneutrino results in JUNO will help to constrain better the current geophysical and geochemical models for the radiogenic element abundances, independently of systematic details.

V. RESULTS FOR HALVED ENERGY-SCALE AND FLUX-SHAPE ERRORS

The reference error bands in Fig. 1 are representative of present state-of-the-art systematic uncertainties on energy-scale and flux-shape deformations of typical reactor event spectra. When one or more JUNO-like experiments will be operative, it is conceivable that the detector energy scale will be subject to dedicated calibration campaigns, and that the reactors spectral profiles will be better understood, on the basis of the high-statistics data sets collected by current-generation short-baseline experiments. Therefore, it makes sense to repeat the analyses in Secs. III and IV in the hypothesis of smaller (for definiteness, halved) error bands in Fig. 1, while all other priors are assumed to be unchanged. The results are discussed below.

FIG. 12: As in Fig. 5, but with halved energy-scale and flux-shape errors.

FIG. 13: As in Fig. 6, but with halved energy-scale and flux-shape uncertainties.

A. Hierarchy tests

Figure 12 is the analogous of Fig. 5, but with halved energy-scale and flux-shape uncertainties. It can be seen that the NH and IH spectra cannot be brought as close to each other as in Fig. 5, and that the residual spectral differences are noticeably larger, as a result of the systematic error reduction.

Figure 13 shows the effect of halving errors on the energy profiles of the energy-scale and flux-shape deformations, corresponding to the best-fit IH spectrum in Fig. 12. From the comparison of Fig. 6 and Fig. 13, it appears that the qualitative behavior of the profiles is similar for either “default” or “halved” errors but, in the latter case, the amplitude is suppressed by roughly a factor of two.

From Figs. 12 and 13, one expects a non-negligible improvement in testing the wrong hierarchy versus the true one. Indeed, Figs. 14 and 15 show the statistical significance of the wrong-hierarchy rejection, in the cases with true NH and true IH, respectively: in both cases, a 3σ rejection level appears to be reachable in about 6 years of data taking, consistently with the expected goal of a JUNO-like experiment [19]. By comparing Figs. 14 and 15 with the

FIG. 14: As in Fig. 7 (true NH), but with halved energy-scale and flux-shape uncertainties.

FIG. 15: As in Fig. 14, but for true IH.

FIG. 16: As in Fig. 9, but with halved energy-scale and flux-shape uncertainties.

FIG. 17: As in Fig. 10, but with halved energy-scale and flux-shape uncertainties.

current estimates, may prevent (in combination) an effective hierarchy discrimination; (3) a future error reductions by a factor of two may lead to a $\gtrsim 3\sigma$ rejection of the wrong hierarchy, with a reasonable detector exposure ($T \simeq 6$ y); (4) a significance $\gtrsim 4\sigma$ seems to be out of reach for a one-decade exposure, unless all systematics are further reduced.

B. Precision physics

Halving the energy-scale and flux-shape uncertainties has also a significant impact on the precision program in a JUNO-like experiment. Figures 16 and 17 (to be compared with the analogous Figs. 9 and 10, respectively), show that such uncertainties, with respect to the case with only oscillation and normalization errors, degrade the final accuracy on the $(\delta m^2, s_{12}^2, \Delta m_{ee}^2)$ parameters by a factor of two or less, while the s_{13}^2 accuracy remains always close to its prior assignment. The constraints on the Th and U geoneutrino flux normalizations (not shown) are basically the same as in Fig. 11, since these spectral components are quite insensitive to details of the energy scale and flux shape.

Table I summarizes the fit results for the oscillation and the geoneutrino parameters, in terms of (symmetrized) 1σ errors, to be compared with their prior $\pm 1\sigma$ ranges. The results refer to NH and to increasing sets of systematic uncertainties, including energy-scale and flux-shape errors at default values (see Figs. 9 and 10) and halved values (see Figs. 16 and 17). In conclusion, reducing the error bands in Fig. 1 represents a major requirement to fully exploit the physics potential of a JUNO-like experiment, both for discriminating the neutrino mass hierarchy and for measuring more precisely the $(\delta m^2, s_{12}^2, \Delta m_{ee}^2)$ oscillation parameters and the geoneutrino fluxes.

TABLE I: Precision physics in a JUNO-like experiment, assuming known normal hierarchy. 1st and 2nd column: oscillation or geoneutrino parameter, together with the assumed prior value and $\pm 1\sigma$ error. 3rd column: 1σ error from the fit to prospective 5-year data, including only oscillation and normalization uncertainties. 4th and 5th column: 1σ error from the fit, including also energy-scale and flux-shape uncertainties with default error bands. 6th and 7th column: as in the previous two columns, but with halved error bands. Similar results are obtained for the case of known inverted hierarchy (not shown). See the text for details.

Parameter	Prior $\pm 1\sigma$	Osc. + norm. fit error	+ energy scale (default)	+ flux shape (default)	+ energy scale (halved)	+ flux shape (halved)
$s_{12}^2/10^{-1}$	3.08 ± 0.17	0.015	0.021	0.040	0.017	0.026
$\delta m^2/10^{-5} \text{ eV}^2$	7.54 ± 0.20	0.016	0.017	0.038	0.016	0.029
$s_{13}^2/10^{-2}$	2.20 ± 0.08	0.073	0.073	0.074	0.074	0.074
$\Delta m_{ee}^2/10^{-3} \text{ eV}^2$	2.40 ± 0.05	0.0036	0.0074	0.011	0.0064	0.0074

VI. SUMMARY AND CONCLUSIONS

Medium baseline, high-statistics reactor neutrino projects such as JUNO (in construction) and RENO-50 (proposed) can pursue an important research program in neutrino physics, including the determination of the unknown mass hierarchy, precision measurements of some known oscillation parameters, and improved constraints on geoneutrino fluxes. In this context, building upon our previous work [20], we have examined in detail the effects of nonlinear variations of the energy scale, $E \rightarrow E'(E)$, and of the unoscillated reactor neutrino flux shape, $\Phi(E) \rightarrow \Phi'(E)$, in addition to the usual prior uncertainties associated to oscillation and normalization parameters. For definiteness, we have performed our analysis in a JUNO-like configuration, assuming energy-scale and flux-shape error bands anchored to state-of-the-art estimates (“default” case), as well as for error bands reduced by a factor of two (“halved” case), as shown in Fig. 1.

It turns out that such systematics can noticeably affect the performance of the experiment, and that their reduction is mandatory in order to achieve statistically significant results, both for hierarchy discrimination and for precision physics. In particular, a $> 3\sigma$ separation of NH and IH might not be reached after one decade in the case of default systematic errors (Figs. 7 and 8), while it can be reached after ~ 6 years of data taking in the case of halved errors (Figs. 14 and 15). Similarly, assuming that the hierarchy is known, the energy-scale and flux-shape systematic uncertainties can significantly affect the accuracy of the $(s_{12}^2, \delta m^2, \Delta m_{ee}^2)$ oscillation parameters emerging from prospective data fits (see Table I).

The main message of our work is that further constraints on the admissible shapes and sizes of $E \rightarrow E'(E)$ and $\Phi(E) \rightarrow \Phi'(E)$ variations would be highly beneficial to the entire physics program of medium-baseline reactor projects. As side results of our analysis, we find that: (1) the well-known IBD energy threshold acts as an effective self-calibration point in the fit; (2) neglecting matter effects may significantly bias the oscillation parameters $(s_{12}^2, \delta m^2)$; (3) taking the wrong hierarchy may significantly bias the parameter Δm_{ee}^2 ; and (4) prospective constraints on Th and U geoneutrino fluxes are largely insensitive to systematic uncertainties.

- [31] In our opinion, it is appropriate to attach flux-shape uncertainties to the “theoretical spectrum” S and energy-scale uncertainties to the “experimental spectrum” S^* . However, we have verified that our results are basically unchanged, if both uncertainties are assumed to act only on S or on S^* . In such cases, in principle, one must also specify the ordering of the non-commutative operations $E \rightarrow E'$ and $\Phi \rightarrow \Phi'$. We have also verified that commuting such operations (on either S or S^*) induces negligible numerical changes in our results.
